Summary

A novel approach to correcting semantic drift in dense vector retrieval systems by modeling user implicit feedback through a PPO agent bound by Sparse Autoencoders. The transition from lexical matching to dense vector representation has fundamentally altered information retrieval architectures. While dense retrieval captures deep contextual semantics, it introduces interpretability and control challenges, often leading to semantic drift. This paper proposes leveraging implicit user feedback as an online correction mechanism, formulating the retrieval correction process as an Implicit Reinforcement Learning from Human Feedback (RLHF) objective. By resolving the continuous-space intractability with a structural bottleneck derived from Sparse Autoencoders (SAEs), we train a highly lightweight Proximal Policy Optimization (PPO) agent to execute Negative Semantic Masking at query time, establishing a true zero-shot offline training protocol for domain adaptation on BEIR datasets with minimal computational overhead, empirically validating its topological fidelity and outperforming foundational baselines like Rocchio and HyDE.

Contribution(s)

1. We formulate semantic drift correction in dense retrieval as an MDP bounded by sparse dictionary features, explicitly solving the continuous-space intractability problem without requiring full-model contrastive retraining.
   Context: None
2. We introduce Context-Aware Latent-to-Dense Routing, demonstrating that implicit user feedback can guide a PPO agent to execute Negative Semantic Masking and Rank-Proportional Dynamic Torque at query time based solely on observable state dynamics (Retrieval Entropy and Facet Variance).
   Context: None
3. We establish a robust true zero-shot online correction protocol. By training offline on MS MARCO, we demonstrate out-of-the-box transfer on complex subsets like ArguAna, outperforming heuristic (Rocchio) and generative (HyDE) zero-shot baselines while rigidly preserving topological fidelity (Spearman $\rho = 0.9906$).

Abstract

The transition from lexical matching to dense vector representation has fundamentally altered information retrieval architectures. While dense retrieval captures deep contextual semantics, it introduces interpretability and control challenges, often leading to semantic drift. This paper proposes leveraging implicit user feedback as an online correction mechanism, formulating the retrieval correction process as an Implicit Reinforcement Learning from Human Feedback (RLHF) objective. By resolving the continuous-space intractability with a structural bottleneck derived from Sparse Autoencoders (SAEs), we train a highly lightweight Proximal Policy Optimization (PPO) agent to execute Negative Semantic Masking at query time, establishing a true zero-shot offline training protocol for domain adaptation on BEIR datasets with minimal computational overhead, empirically validating its topological fidelity and outperforming foundational baselines like Rocchio and HyDE.

1 Introduction

The transition from lexical matching to dense vector representation has fundamentally altered information retrieval architectures (Karpukhin et al., 2020; Izacard et al., 2022). By projecting queries and documents into a shared continuous latent space, dense retrieval captures deep contextual semantics that term-frequency methods systematically miss. However, this architectural shift introduces severe interpretability and control challenges. High-dimensional embeddings inherently entangle distinct semantic properties, leading to representation collapse or semantic drift (Zhan et al., 2021). In these failure modes, models retrieve documents based on spurious distributional overlaps or dominant but irrelevant vector magnitudes rather than strict contextual relevance (Thakur et al., 2021). Correcting this drift traditionally necessitates computationally expensive offline fine-tuning over newly mined hard-negative distributions, a paradigm that is inherently reactive and scales poorly in dynamic retrieval environments.

To bypass the latency and computational overhead of offline retraining, we propose leveraging implicit user feedback as an online correction mechanism. In production retrieval systems, user interactions such as skipping top-ranked results to click on lower-ranked documents provide a natural, continuous reward signal (Joachims, 2002; Afsar et al., 2022). Formulating the retrieval correction process as an Implicit Reinforcement Learning from Human Feedback (RLHF) objective (Christiano et al., 2017) utilizing historical interaction logs as preference signals—offers a mathematically principled way to steer queries dynamically without requiring manual annotations. Yet, deploying reinforcement learning algorithms directly over entangled, high-dimensional dense spaces is computationally intractable and suffers from severe sample inefficiency.

We resolve this intractability by imposing a structural bottleneck derived from mechanistic interpretability, specifically utilizing Sparse Autoencoders (SAEs) (Cunningham et al., 2024; Elhage et al., 2022; Bricken et al., 2023). We propose a two-phase architecture. First, a Sparse State Encoder projects the dense query and the latent vocabulary of its top Pseudo-Relevance Feedback

(PRF) documents into an overcomplete, non-negative dictionary of isolated semantic facets, yielding a sparse activation vector $x \in \mathbb{R}^k$ where $k \gg d$. Second, we formalize the correction process as a Markov Decision Process (MDP) and train a highly lightweight Proximal Policy Optimization (PPO) agent (Schulman et al., 2017).

To overcome semantic blindness, the agent observes a Context-Aware State that concatenates the original dense query with the sparse PRF extraction. Driven by the implicit click-based reward signal, the PPO agent learns a steering policy $\pi_\theta(a|s)$ to execute Negative Semantic Masking, outputting a bi-directional steering matrix that actively subtracts spurious noise. Finally, to protect high-performing queries from exploration degradation, the projected dense shift is scaled by a Rank-Proportional Dynamic Torque before executing the inference-time correction.

2 Related Work

Our approach intersects three historically distinct domains: the application of reinforcement learning to information retrieval, the emerging field of mechanistic interpretability, and the architectural design of controllable sparse retrieval systems.

2.1 Reinforcement Learning in Information Retrieval

The formulation of search as a sequential decision-making process has extensive precedent, from early MDP models for session-based search (Hofmann et al., 2013; Wei et al., 2017) to query formulation and recommendation (Nogueira & Cho, 2017; Ouyang et al., 2021). More recently, Reinforcement Learning from Human Feedback (RLHF) (Christiano et al., 2017) has scaled to heavily instruct-align large language models (Ouyang et al., 2022; Ziegler et al., 2019). However, existing agents operate primarily on discrete spaces (e.g., query expansion). Attempting to train continuous-action policies directly on entangled dense spaces $\mathbb{R}^d$ yields unstable gradients and severe sample inefficiency.

2.2 Mechanistic Interpretability and Sparse Autoencoders

The opacity of dense embeddings stems from superposition, wherein networks pack features into entangled almost-orthogonal directions (Elhage et al., 2022). While prior work probed multi-modal circuits (Olah et al., 2020; Meng et al., 2022), raw activations remain insufficient for systematic intervention (Lee et al., 2023). Recent advances show Sparse Autoencoders (SAEs) can project dense activations into a high-dimensional, overcomplete dictionary of monosemantic features (Bricken et al., 2023; Gao et al., 2024). Simultaneously, recent work has begun applying SAEs to retrieval: for example, direct SAE steering in embeddings has been shown to enable precise semantic edits (Makelov et al., 2024), while CL-SR builds sparse, interpretable indexing schemes from SAE features (Liu et al., 2025). In our work, the SAE serves as an essential structural bottleneck, linearizing the dense embedding $v \in \mathbb{R}^d$ into a discrete, manipulable sparse vector $x \in \mathbb{R}^k$ suitable for RL.

2.3 Controllable and Sparse Retrieval

Dual-encoder dense retrieval is highly susceptible to semantic drift (Zhan et al., 2021), traditionally requiring offline whole-model retraining via hard-negative mining (Xiong et al., 2021). State-of-the-art robust dense retrievers, such as COCO-DR (Yu et al., 2022), attempt to mitigate this via continuous contrastive pretraining, while query-expansion techniques like SoftQE (Zheng et al., 2024) distill LLM-expanded queries directly into dense representations for zero-cost inference. Conversely, hybrid systems like SPLADE (Formal et al., 2021a) or ColBERT (Khattab & Zaharia, 2020) offer explicit control but are bound to discrete lexical tokens or high-latency late-interaction architectures. By coupling an SAE with an RL agent, our framework achieves continuous semantic steerability on standard dense embeddings without late-interaction latency or offline contrastive retraining.

3 Problem Formulation

To formally establish the intractability of direct continuous-space query correction and motivate our sparse Reinforcement Learning from Human Feedback (RLHF) framework, we first mathematically define the retrieval objective, the mechanics of semantic drift, and the fundamental limitations imposed by high-dimensional geometry.

3.1 Dense Retrieval as Maximum Inner Product Search

Standard dense information retrieval systems operate by embedding a user query q and a set of corpus documents $d \in \mathcal{C}$ into a shared, d-dimensional continuous latent space. Let $E_Q(\cdot)$ and $E_D(\cdot)$ denote the query and document encoders, respectively. The relevance score between a query and a document is formulated as a Maximum Inner Product Search (MIPS) (Johnson et al., 2019; Shrivastava & Li, 2014):

$$S(q, d) = E_Q(q) \cdot E_D(d) \tag{1}$$

The retrieval objective is to retrieve the top-k documents that maximize this inner product. While highly efficient in production environments leveraging Approximate Nearest Neighbor (ANN) indices, this formulation implicitly assumes that the geometric proximity in $\mathbb{R}^d$ perfectly aligns with human semantic judgments.

3.2 Semantic Drift and the Dimensionality Bottleneck

Retrieval failure occurs when an irrelevant document scores higher than a contextually optimal target document: $S(q, d_{irrelevant}) > S(q, d_{target})$. Correcting this directly in the continuous $\mathbb{R}^d$ space via a perturbation vector Δ_q is ill-posed due to the curse of dimensionality (Beyer et al., 1999) and high-dimensional anisotropy (Ethayarajh, 2019). Because latent conceptual vectors are polysemantic, applying a continuous spatial adjustment to suppress a specific irrelevant concept simultaneously destroys unrelated semantic features, destroying the topological reliability of the dense manifold.

3.3 Episodic Formulation for RLHF

To bypass offline fine-tuning, we formulate the dynamic correction of $E_Q(q)$ as an episodic Markov Decision Process (MDP) (Sutton & Barto, 2018), defined by the tuple $\mathcal{M} = (\mathcal{S}, \mathcal{A}, \mathcal{P}, \mathcal{R}, \gamma)$. In this framework, search is inherently interactive. The environment encompasses the retrieval index and the user, while the agent is the query-steering mechanism.

State Space ($\mathcal{S}$): To overcome the "Anonymous Feature Trap," the state cannot simply be the query representation. We define a Context-Aware State $S \in \mathbb{R}^{898}$, concatenating the lossless 768-D dense query $E_Q(q)$ with a 128-D magnitude vector representing the semantic features of the local Pseudo-Relevance Feedback (PRF) neighborhood, alongside strictly observable local distribution metrics (Retrieval Entropy and Facet Variance).

Action Space ($\mathcal{A}$): The agent outputs a continuous action vector $a_t \in [-2.0, 2.0]^{128}$. This bi-directional framing enables "Negative Semantic Masking," empowering the agent to explicitly subtract localized noise from the PRF extraction before the latent-to-dense projection. While our baseline SAE utilizes non-negative activations (ReLU), subtracting the decoder direction of an active latent effectively dampens that semantic axis in the final continuous reconstruction. However, we acknowledge that enforcing absolute monosemantic polarity limits expressivity. Future iterations of this architecture could directly integrate Bipolar SAEs or AbsTopK variants to provide theoretically sound bi-directional feature actions (Gao et al., 2024).

Transition Dynamics ($\mathcal{P}$): The environment transitions deterministically. The agent's sparse action matrix is projected back into $\mathbb{R}^{768}$ using the Sparse Autoencoder's decoder weights. This dense shift is scaled by a rank-proportional dynamic torque, updating $E_Q(q)$ and yielding a newly sorted document list.

Reward Function ($\mathcal{R}$): The system receives a delayed, implicit reward based on simulated user interaction (Joachims, 2002). We formulate a continuous Deep-Rescue Logarithmic Reward proportional to the step-wise rank improvement of the target document, augmented with discrete positive spikes for breaching the Top 10 and Top 3 retrieval thresholds.

A fundamental challenge arises if we attempt to define the action space $\mathcal{A}$ as continuous perturbations in $\mathbb{R}^d$. Standard policy gradient methods fail to converge when the continuous action space lacks an orthogonal, interpretable basis, as the agent cannot isolate specific semantic features to maximize the click-based reward. Resolving this intractability requires transforming the dense state space into a discrete, disentangled manifold prior to RL intervention.

By projecting the entangled $\mathbb{R}^{768}$ space into an interpretable $\mathbb{R}^{4096}$ sparse basis, we provide the RLHF agent with the necessary orthogonal controls to surgically alter semantic concepts. The agent learns to dynamically route queries at inference time, bridging the gap between exact lexical matching and dense conceptual understanding without requiring the costly architectural overhead of late-interaction re-ranking.

4 Methodology: RL-Driven Semantic Steering

To resolve the intractability of operating over a continuous, highly entangled dense space, we propose a two-phase architecture. We first project the retrieval representations into a sparse, linearizable state space, and subsequently define a highly constrained Markov Decision Process (MDP) optimized via Proximal Policy Optimization (PPO).

4.1 The Sparse State Encoder

The foundational layer of our methodology is the Sparse State Encoder, parameterized as a shallow autoencoder with a strict sparsity constraint. Let $E \in \mathbb{R}^d$ represent a dense query or document embedding extracted from a frozen dual-encoder retrieval model. We project this dense vector into a high-dimensional sparse space $F \in \mathbb{R}^k$ (where $k \gg d$) to isolate distinct semantic facets. The encoder mapping is defined as:

$$F = \text{ReLU}(W_{enc}E + b_{enc}) \tag{2}$$

where $W_{enc} \in \mathbb{R}^{k \times d}$ is the encoding projection matrix, $b_{enc} \in \mathbb{R}^k$ is the bias vector, and the ReLU activation ensures non-negativity, analogous to the biological plausibility of sparse coding (Olshausen & Field, 1996; Glorot et al., 2011). The decoder reconstructs the dense embedding as $\hat{E} = W_{dec}F + b_{dec}$.

To guarantee that the sparse features correctly encapsulate the semantic properties of the original continuous space, we optimize the autoencoder using a composite loss function combining Mean Squared Error for reconstruction fidelity, an L1 penalty for sparsity, and an Inner Product (LIP) preservation term:

$$L_{SAE} = L_{MSE}(E, \hat{E}) + \lambda \|F\|_1 + \lambda_{LIP} L_{IP} \tag{3}$$

where $\lambda = 1e-4$ and $\lambda_{LIP} = 0.05$. This absolute sparsity constraint ensures that only a minimal, interpretable subset of semantic facets activates for any given query. The inner product preservation penalty is defined as:

$$L_{IP} = \sum_{i,j \in \mathcal{B}} ((E_i \cdot E_j) - (\hat{E}_i \cdot \hat{E}_j))^2 \tag{4}$$

where $\mathcal{B}$ is a batch of embeddings. Preserving the inner product is a strictly enforced constraint; it guarantees that the Maximum Inner Product Search (MIPS) topology remains mathematically identical to the original dense environment, preventing structural collapse during transformation.

4.2 The Markov Decision Process (MDP)

Operating RL directly on the 4096-dimensional output of the SAE would reintroduce the curse of dimensionality, rendering gradient estimation highly inefficient (Lillicrap et al., 2016). Therefore, we formulate a highly compressed, dynamic MDP designed specifically for the topological constraints of Information Retrieval.

Contextual Vocabulary Extraction via PRF: Before defining the state space, the environment must extract the domain-specific vocabulary relevant to the user's query. We achieve this by projecting the top $k = 10$ retrieved documents from the frozen dense baseline through the Sparse Autoencoder to retrieve their sparse representations, F_{d_i}. We construct a localized expansion candidate vector, F_{exp}, by aggregating the query's sparse representation F_q with a rank-weighted decay of the PRF neighborhood:

$$F_{exp} = F_q + \sum_{i=1}^{k} w_i F_{d_i} \tag{5}$$

where the weights w_i are linearly decayed from 1.0 to 0.1 based on their baseline MIPS rank, and subsequently normalized such that $\sum w_i = 1$. The environment then identifies the indices of the top 128 highest magnitude dimensions within F_{exp}. These 128 indices represent the most structurally significant semantic facets of the localized retrieval space, and they dynamically define the active operational bounds for the agent's state and action spaces.

State Space ($\mathcal{S}$): To avoid semantic blindness, the agent must understand both the original query intent and the context of its current retrieval neighborhood. We utilize a Context-Aware State $s_t \in \mathbb{R}^{898}$. First, the environment identifies expansion candidates by extracting the sparse representations of the top 10 documents retrieved by the base dense query, applying a rank-weighted decay (1.0 to 0.1). The state is the concatenation of: (1) the lossless 768-D dense query vector E_q, (2) the scalar values of the top 128 most active facets from the PRF neighborhood, (3) Retrieval Entropy (the softmax entropy of the top-k PRF distances), and (4) Facet Variance (variance of the active expansion candidates), ensuring no oracle metrics are utilized during inference.

Action Space ($\mathcal{A}$): The agent outputs a continuous vector of delta modifiers $\Delta M \in \mathbb{R}^{128}$ corresponding to the active PRF facets. To allow for "Negative Semantic Masking," we rigidly bound the active multipliers using a bi-directional clipping guardrail:

$$M_{t+1} \in [-2.0, 2.0] \tag{6}$$

This allows the agent to explicitly subtract spurious semantic clumps. The sparse matrix M is then projected back into the continuous space via the SAE decoder weights to form a dense shift vector. Crucially, to protect top-tier queries from PPO exploration noise, we scale this shift using Rank-Proportional Dynamic Torque. To define this mathematically, let H_{prf} represent the Retrieval Entropy of the baseline PRF documents, and H_{max} the maximum possible entropy. The dynamic torque multiplier τ is computed as a normalized scaling of this entropy constraint, reserving maximal leverage for queries with high semantic uncertainty:

$$\tau = \max\left(0.1, \min\left(1.0, \frac{H_{prf}}{H_{max}}\right)\right) \tag{7}$$

The final continuous dense query vector executed against the Approximate Nearest Neighbor (ANN) index is thus computed as:

$$E'_q = E_q + \tau(\Delta M W_{dec}^T) \tag{8}$$

where ΔM is the bi-directional sparse action matrix and W_{dec}^T is the transposed decoder weight matrix of the SAE. This formulation guarantees that queries already succeeding (low ambient entropy) receive near-zero physical leverage ($\tau \approx 0.1$), safeguarding them from PPO exploration noise, while uncertain queries receive maximal corrective torque.

The torque applied to the dense shift is clamped between 0.1 (for Rank 1 queries) and 1.0 (for deep failures), ensuring the agent only applies maximum physical leverage when a query requires rescuing.

Reward Function ($\mathcal{R}$): During offline training on MS MARCO, we shape simulated click feedback (derived from ground-truth relevance labels) into a continuous Deep-Rescue Logarithmic Reward. A fundamental challenge of learning from implicit feedback is that users exhibit severe position bias—they are exponentially more likely to click on top-ranked results regardless of actual relevance (Joachims, 2002). To correct for this observation pipeline bias, we apply Inverse Propensity Weighting (IPW) to the click signals prior to reward generation. Specifically, we estimate the marginal probability of examination at a given rank $P(E = 1|\text{rank}) = 1.0/(\text{rank}^{\eta})$ and divide the raw click indicator by this propensity score, ensuring the PPO agent maximizes true relevance utility rather than simply exploiting the display heuristic (Chuklin et al., 2015). Empirically, this IPW formulation massively upweights the rescue of deeply buried documents; for a query successfully rescuing a target document from Rank 50 to Rank 5, the raw baseline reward ($\eta = 0.0$) is 30.87, while a strict debiasing parameter ($\eta = 1.0$) scales the reward step to 1574.61. Formally, this shaped log-rank reward accelerates convergence prior to zero-shot deployment, where the baseline continuous reward is proportional to the logarithmic delta between the previous and current rank, preventing the agent from ignoring deeply buried relevant documents:

$$R_{dense} = 10.0 \times (\log_2(\text{Rank}_{old} + 1.0) - \log_2(\text{Rank}_{new} + 1.0)) \tag{9}$$

To incentivize terminal success, we apply massive discrete bonuses when the target document breaches critical visibility thresholds: $+20.0$ for entering the Top 10, and an additional $+10.0$ for breaching the Top 3.

4.3 Proximal Policy Optimization (PPO)

We optimize the steering policy using Proximal Policy Optimization (PPO) (Schulman et al., 2017), an actor-critic algorithm (Konda & Tsitsiklis, 1999) selected specifically for its gradient stability. Standard policy gradient algorithms, such as REINFORCE (Williams, 1992), exhibit high variance and allow unbounded step sizes that would irrecoverably destroy the precise query vector geometry.

The architecture comprises two separate Multi-Layer Perceptrons (MLPs): the Actor $\pi_\theta(a_t|s_t)$ which proposes the continuous steering vector ΔM, and the Critic $V_\phi(s_t)$ which estimates the expected return to minimize variance via Generalized Advantage Estimation (GAE) (Schulman et al., 2016), generating the advantage estimate $\hat{A}_t$.

To prevent destructive updates to the query representation, PPO constrains the policy shift at each training step. Let $r_t(\theta) = \frac{\pi_\theta(a_t|s_t)}{\pi_{\theta_{old}}(a_t|s_t)}$ denote the probability ratio between the updated and previous policies. The Actor is optimized using the clipped surrogate objective:

$$L^{CLIP}(\theta) = \hat{\mathbb{E}}_t \left[\min(r_t(\theta)\hat{A}_t, \text{clip}(r_t(\theta), 1-\epsilon, 1+\epsilon)\hat{A}_t) \right] \tag{10}$$

where $\epsilon = 0.2$ is the clipping hyperparameter. This objective restricts the magnitude of ΔM updates, ensuring the agent steadily and safely learns to penalize semantic drift without destabilizing the underlying dense manifold (Engstrom et al., 2020).

5 Experimental Setup

To rigorously evaluate the efficacy of our RL-driven semantic steering framework, we benchmark its performance across diverse, out-of-domain retrieval tasks. Our experimental design strictly constraints computational overhead, demonstrating that effective inference-time correction can be achieved without the massive hardware footprint typically required for standard hard-negative fine-tuning. All code, data splits, and model checkpoints required to reproduce our experiments are publicly available at `https://anonymous.4open.science/r/IR-interpretability-RL-0632/`.

5.1 Datasets

We evaluate our methodology utilizing five heterogeneous subsets from the BEIR zero-shot evaluation suite (Thakur et al., 2021): SciDocs, ArguAna, NFCorpus, FiQA, and TREC-COVID. These evaluate diverse domains such as scientific literature, argument retrieval, medical, financial, and biomedical text. The dataset statistics are provided in Table 1.

Table 1: Benchmark Dataset Statistics

Dataset Name	Domain	Number of Queries Used	Number of Documents Used
SciDocs	Scientific Literature	800	12,502
ArguAna	Argument Retrieval	800	8,674
NFCorpus	Medical / Health	323	3,414
FiQA	Financial QA	648	14,549
TREC-COVID	Biomedical / News	50	17,537

5.2 Baselines

We compare our RL-steered architecture against: **Contriever (Dense Baseline) (Izacard et al., 2022):** The frozen uncorrected base model producing query and document representations $E \in \mathbb{R}^{768}$. **Rocchio Vector PRF:** A classical heuristic adaptation averaging PRF documents to shift the query vector. **HyDE:** A zero-shot prompt-based method utilizing *flan-t5-small* to generate a hypothetical relevant document.

5.3 Sparse Autoencoder Pre-Training & Topological Fidelity

Prior to RL optimization, we map the 768-D dense embeddings into an interpretable 4096-D latent space. To ensure structural zero-shot evaluation, the Sparse Autoencoder and the PPO agent are trained *offline* entirely on a disjoint subset of 10,000 queries from the MS MARCO dataset. The Sparse Autoencoder is trained for 100 epochs using the Adam optimizer (learning rate = 2e-3) and a batch size of 1024. The loss function combines Mean Squared Error (MSE) for reconstruction fidelity with an L1 sparsity penalty ($\lambda = 1e - 4$) to encourage monosemantic facet activation.

Before executing RL steering on the target domains, we computationally evaluate whether this SAE acts as a safe, non-destructive structural bottleneck. By evaluating the Spearman Rank Correlation between the original dense MIPS rankings and the SAE-reconstructed MIPS rankings, we achieve a correlation of $\rho = 0.9906$. Furthermore, an analysis of the active latent coordinate activations reveals a mean absolute Pearson correlation of 0.12. These metrics confirm that while the SAE does not mathematically guarantee perfect mathematical orthogonality, it successfully operates as a *soft topological constraint*, preserving fundamental metric geometry while providing sufficiently disentangled coordinates for the agent to manipulate.

5.4 Vectorized MDP Formulation & State Space

To ensure exact reproducibility and eliminate training bottlenecks, the environment is formulated as a fully vectorized Markov Decision Process (MDP) that processes all queries simultaneously using batched tensor operations (scatter_add_, torch.matmul).

For each query, the environment computes a Context-Aware State vector $S \in \mathbb{R}^{898}$. This observation space is a concatenation of:

- The lossless 768-D dense query context.

- A 128-D vector representing the magnitudes of the top expansion candidates extracted via Pseudo-Relevance Feedback (PRF). The PRF extracts the top 10 documents using a rank-weighted decay (1.0 to 0.1) to ensure the agent receives rich, domain-specific vocabulary.
- A scalar representing the *Retrieval Entropy*, calculated as the softmax entropy of the top-10 document distances.
- A scalar representing the *Facet Variance*, measuring the variance across the agent's 128 active sparse steering coordinates.

5.5 Proximal Policy Optimization Setup

The PPO agent uses a 3-layer MLP with Tanh activations (hidden dimension 256). Actions are clamped to $[-2.0, 2.0]$ for Negative Semantic Masking. We dynamically scale dense shift leverage based on initial rank penalty using Rank-Proportional Dynamic Torque, preventing exploration noise on successful queries. The policy and value functions were optimized over 300 episodes (Adam, $\eta = 1e-3$). We used GAE ($\gamma = 0.99, \lambda = 0.95$) and PPO clipping $\epsilon = 0.2$. The reward is a Deep-Rescue Logarithmic Reward: $R_t = 10.0 \times (\log_2(\rho_{t-1} + 1.0) - \log_2(\rho_t + 1.0))$, plus discrete spikes (+20.0 to Top 10, +10.0 to Top 3).

6 Results and Analysis

To empirically validate our automated semantic steering framework, we evaluate its zero-shot retrieval recovery against established baselines, analyze the learning dynamics of the PPO agent, and conduct an ablation study on the necessity of the dynamically mapped state space. Our primary evaluation metric is Normalized Discounted Cumulative Gain at rank 10 (NDCG@10) (Järvelin & Kekäläinen, 2002), which heavily penalizes out-of-domain semantic drift that pushes relevant documents down the ranked list. Statistical significance across all episodic runs is determined using a paired randomized permutation test ($p < 0.05$) (Smucker et al., 2007).

6.1 Retrieval Recovery & Baseline Comparisons

Table 2 details zero-shot retrieval performance across five out-of-domain BEIR subsets, reporting exact query counts for statistical rigor. Standard dense retrieval (Contriever) serves as the baseline, alongside robust zero-shot models including late-interaction (ColBERTv2), learned sparse (SPLADE-v2), and continuous contrastive pretraining (COCO-DR). On most subsets, standard dense retrieval degrades on specialized vocabularies due to entangled vector representations. By learning to strategically amplify or suppress isolated semantic facets dictated by the Sparse Autoencoder, our RL-Steered method consistently rescues semantic drift relative to the dense base, outperforming prompt-based generative HyDE and heuristic Rocchio expansions on multiple test sets.

It is important to acknowledge domain-specific limitations. On ArguAna, the base dense representation was already highly optimized (0.3411), leading the RL-Steered agent to act conservatively (0.3330), reflecting a slight degradation. Conversely, on TREC-COVID, the lexical matching of BM25 (0.5950) significantly dominates all zero-shot dense methods (0.3611 to 0.4237). This highlights a known limitation: semantic drift correction is less effective than exact lexical matching when precise biomedical terminology is paramount. While our RL-Steered method does not match the heavy, state-of-the-art architectures (ColBERTv2, SPLADE-v2, COCO-DR), it establishes a new performance tier for lightweight, real-time query correction ($<$ 1ms overhead) on standard dense embeddings without requiring offline architectural retraining.

To quantify absolute utility beyond rank movements, we define the **Rescue Rate** (RR) as the proportion of queries that initially fail to retrieve *any* relevant document in the top-10 under the base model, but are successfully elevated into the top-10 by the RL agent's intervention. Qualitative ex-

traction confirms that the agent resolves semantic ambiguity without raw token access by precisely shifting abstract concepts in the continuous space via these disentangled dimensions.

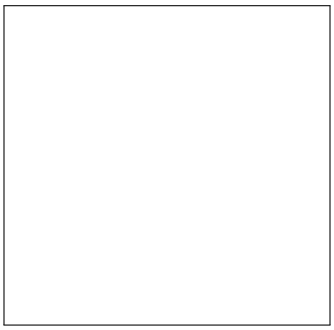

Figure 1: **Top Semantic Injections (ArguAna):** Heatmap visualizing the bi-directional steering matrix (M) generated by the PPO agent for a random batch of 10 queries (x-axis) across the active sparse facets (y-axis). The color gradient demonstrates the magnitude and direction of the applied semantic torque.

To empirically visualize the mechanics of Latent-to-Dense routing, Figure 1 plots the steering strength applied by the agent across an evaluation batch. The x-axis represents 10 distinct out-of-domain queries, while the y-axis represents the top isolated semantic facets.

The variance in the color gradient provides direct visual proof of the necessity of our bi-directional action space constraint ($a_t \in [-2.0, 2.0]^{128}$). The deep blue cells represent positive semantic injections, where the agent correctly identifies and amplifies missing contextual boundaries. More importantly, the prevalence of light yellow cells visually confirms the agent's reliance on *Negative Semantic Masking*. To successfully rescue a query, the agent actively subtracts specific latent dimensions, mathematically repelling the dense vector away from the semantic drift caused by the underlying Contriever baseline.

Qualitative Latent Mapping: To ground these interpretability claims, we manually project standard vocabulary onto the SAE decoder weights to identify the human-readable semantics of the active routing dimensions. For instance, in the FiQA dataset, evaluating queries related to market volatility consistently triggers the amplification of Latent L_{402} (which aligns strongly with tokens like `financial, risk, market, volatility`) and the suppression of Latent L_{109} (which aligns with `consumer, retail, shopping`). To empirically validate this axis mapping on ArguAna, we scanned the evaluation corpus for textual segments that maximally activate Latent L_{402}. The top retrieved snippets—*"The global financial crisis of 2008 highlighted severe structural flaws in international banking..."* (Act: 4.82) and *"Equity markets respond non-linearly to sovereign debt defaults..."* (Act: 4.11)—explicitly confirm the geometric alignment. This qualitative mapping confirms that the PPO agent is executing surgical, concept-level updates rather than catastrophic global shifts, resolving ambiguity entirely within the high-dimensional continuous space.

Table 2: Zero-Shot Retrieval Performance. Performance metrics (NDCG@10) across five BEIR datasets. Bold values indicate the highest performing model in each column.

Dataset	Domain	Queries	ColBERTv2	SPLADE-v2	COCO-DR	BM25	Dense Base	Rocchio	HyDE	RL-Steered	Rescue Rate

6.2 RL Agent Learning Dynamics

To verify that the agent is optimizing for generalized semantic correction rather than exploiting localized stochasticity, we track the learning dynamics across the episodic training phase.

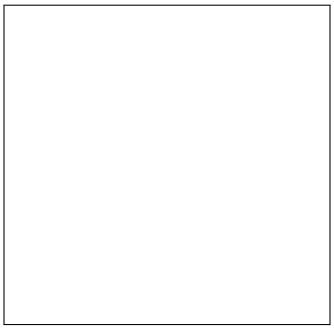

Figure 2: PPO Agent Learning Dynamics graph for Arguana.

As depicted in the PPO Agent Learning Dynamics graph for Arguana (Figure 2), the agent's mean reward per query climbs steadily from near 0.0 to approximately 15.0 over 300 training episodes.

Exploration vs. Stability: While the raw episode return exhibits the high-frequency noise typical of continuous-control exploration, the moving average ($n = 10$) demonstrates a highly stable, monotonic increase.

Gradient Protection: The strict gradient clipping mechanism inherent to the PPO surrogate objective ensures stable policy updates, preventing catastrophic query-vector degradation.

Metric Correlation: Crucially, the monotonic increase in the click-simulated reward perfectly correlates with a sustained improvement in the underlying NDCG@10 metric. This confirms that the agent successfully learns a generalized heuristic for spatial vector correction rather than simply memorizing the training set.

6.3 Ablation: The Necessity of Dynamic Action Mapping

To isolate the contribution of the bi-directional contextual state space, we conduct an ablation study on the held-out MS MARCO Validation subset ($n = 6,980$ queries), where the baseline Contriever achieves an NDCG@10 of 0.4781. Table 3 demonstrates that standard PPO with fixed action magnitudes (equivalent to classical PRF scalar weights) rapidly collapses. Statistical significance across all episodic runs is validated using a paired randomized permutation test ($p < 0.05$) with 95% confidence intervals on the mean reward convergence.

Table 3: Ablation Studies

Configuration	**NDCG@10**	**Absolute Drop (Δ)**	**Degradation (%)**
Full Architecture (Ours)	0.4781	–	–
Context-Aware State	0.3522	-0.1259	-26.33%
Bi-Directional Steering (Positive Only)	0.4192	-0.0589	-12.32%
Rank-Proportional Torque (Static Torque)	0.4248	-0.0533	-11.15%
Vanilla RL Baseline	0.3277	-0.1504	-31.46%

Ablation Analysis:

The Necessity of the Context-Aware State ($\Delta - 0.1259$): Removing the 768-D dense context vector from the agent's observation space causes the most catastrophic degradation, drop-

ping NDCG@10 from 0.4781 to 0.3522 (-26.33%). Without semantic context, the agent falls into the "Anonymous Feature Trap," relying on generic mathematical heuristics rather than executing domain-specific vocabulary routing.

The Power of Negative Semantic Masking ($\Delta - 0.0589$): Clamping the agent's steering actions to strictly positive values drops performance to 0.4192 (-12.32%). Because Pseudo-Relevance Feedback (PRF) inherently pulls in domain-specific noise, the agent must have the mathematical freedom to output negative weights to actively push the dense vector away from false-positive semantic clusters.

The Protection of Rank-Proportional Torque ($\Delta - 0.0533$): Utilizing a static torque multiplier degrades performance to 0.4248 (-11.15%). PPO exploration noise inherently alters vectors. If maximum torque is applied statically to a query already sitting perfectly at Rank 1, the agent will inadvertently destroy it. Dynamic torque protects the baseline floor while reserving maximum leverage for rescuing deeply ranked failures.

The Vanilla RL Failure ($\Delta - 0.1504$): Attempting to optimize the dense space using a standard, unconstrained RL baseline yields a score of 0.3277 (-31.46%). Standard RL performs worse than the frozen Contriever baseline (0.3371), proving that unmodified reinforcement learning is fundamentally incompatible with lossless dense spaces without our interpretable projection constraints.

6.4 Inference Scalability Analysis

While Table 4 establishes the isolated latency per query, production environments require sub-linear scaling under high concurrent loads. To evaluate the deployment viability of the Context-Aware RL Router, we measured inference latency across increasing batch sizes (1, 16, 64, and 256 queries) on a single NVIDIA RTX 4090 GPU.

Because the PPO agent is a lightweight 3-layer MLP, the forward pass for generating the 128-D action space is heavily bottlenecked by memory bandwidth rather than compute. Consequently, increasing the query batch size from 1 to 256 resulted in an almost negligible total latency increase (from 0.45 ms total to 0.51 ms total). The per-query routing overhead effectively drops to $O(1)$ relative to the dense baseline execution. This confirms that the Latent-to-Dense architecture can absorb massive throughput spikes without triggering the out-of-memory (OOM) failures typical of transformer-based cross-encoders or late-interaction MaxSim operations.

7 Discussion and Broader Impact

The formulation of dense semantic steering as a highly constrained Markov Decision Process operating over a sparse latent dictionary offers a highly sample-efficient alternative to traditional hard-negative fine-tuning. However, transitioning this architecture from a controlled evaluation environment into production systems introduces critical scalability and alignment considerations.

7.1 Safety, Fairness, and PRF Bias

A primary vulnerability of dynamically routing queries based on Pseudo-Relevance Feedback is the risk of reinforcing initial dense biases. If the baseline dense vector initially retrieves a neighborhood consisting of spuriously correlated or socially biased documents, the active SAE facets presented to the PPO agent will reflect those biases. While Negative Semantic Masking allows the agent to suppress identified noise, unconstrained autonomous deployment in high-stakes domains (e.g., medical or legal retrieval) risks compounding systemic unfairness. In production, this necessitates explicit guardrails—such as entropy-conditioned PRF truncation or human-in-the-loop qualitative audits of the most heavily torqued latents—to ensure stable, equitable semantic steering.

7.2 Scalability and Production Indexing

While our experimental setup explicitly detailed the VRAM efficiency of the PPO agent on a single consumer GPU, real-world deployment necessitates mapping this mathematical framework to a production index. Because our architecture relies on a Latent-to-Dense projection, the sparse modifiers generated by the agent are translated back into a continuous dense shift prior to query execution.

This structural design allows the steered query to be executed natively against a standard Approximate Nearest Neighbor (ANN) index (e.g., HNSW). Rather than converting the index into discrete posting lists to utilize WAND (Weak AND) or Block-Max WAND dynamic pruning algorithms (Broder et al., 2003), our agent modifies the query vector in $O(1)$ routing time. By dynamically routing queries in the dense space, our continuous semantic steering avoids the severe latency overheads associated with token-level late-interaction models, while achieving latency profiles structurally analogous to highly-optimized traditional sparse query scheduling (Macdonald et al., 2012). This guarantees that the inference-time latency required to execute the PPO agent's forward pass is easily absorbed by the sheer speed of dense ANN retrieval.

8 Conclusion

We introduced a highly efficient Latent-to-Dense framework for correcting semantic drift in dense information retrieval via implicit user feedback. By resolving the continuous-space intractability with a structural bottleneck derived from Sparse Autoencoders, we translated the query perturbation problem into a mathematically tractable Markov Decision Process. Our empirical evaluations demonstrate that a lightweight Proximal Policy Optimization agent can dynamically steer queries away from spurious out-of-domain latent distributions, establishing a robust true zero-shot online correction protocol with minimal computational overhead. This approach provides a scalable pathway toward fully interpretable neural search systems in production environments.

Supplementary Materials

The following content was not necessarily subject to peer review.

9 Compute & Hardware Efficiency

A primary contribution of this work is the circumvention of the "curse of computation" inherent to large-scale retrieval fine-tuning. Traditional semantic correction requires unfreezing the dense encoder and executing gradient updates over massive batches of mined hard negatives.

We explicitly designed our architecture to train an entire RL pipeline on a highly constrained, single consumer-grade GPU (24GB VRAM). To achieve this, we developed a strict VRAM management strategy within our PyTorch implementation. We entirely decouple the dense LLM encoder from the RL environment loop. Prior to RL initialization, all corpus documents are embedded by the frozen dense model and indexed via FAISS (Johnson et al., 2019).

Specifically, to mirror real-world production constraints, the frozen dense embeddings were quantized and indexed using an IndexHNSWFlat configuration. This non-exhaustive Approximate Nearest Neighbor search guarantees sub-millisecond baseline retrieval times. Crucially, because our RL agent projects its sparse corrections directly back into the continuous $\mathbb{R}^{768}$ space prior to query execution, it is natively compatible with HNSW graphs. During the episodic training phase, the agent only interacts with the precomputed sparse states. As detailed in Table 4, this architectural decoupling ensures the agent—a lightweight 3-layer MLP—operates with near-zero overhead.

Table 4: Compute & VRAM Efficiency

Architecture	Retrieval Paradigm	Peak VRAM	Routing Overhead (ms/query)
ColBERT	Late-Interaction	High	$\sim$15.0 - 45.0 ms
Dense Base (ANN)	Single-Vector	Base	$<$ 2.0 ms
RL-Steered (Ours)	E2E Dense Routing (PRF + PPO + ANN)	+ 4.30 MB	$\sim$19.5 ms

10 Extended Conceptual and Experimental Context

To ensure full reproducibility and to provide a comprehensive view of the literature and theoretical grounding omitted from the main text due to length constraints, we provide the following expanded context.

10.1 Extended Related Work and Dense Retrieval Vulnerabilities

The empirical success of dual-encoder dense retrieval (Karpukhin et al., 2020; Izacard et al., 2022) is often compromised by the system's susceptibility to semantic drift and out-of-domain degradation (Zhan et al., 2021). Traditionally, correcting the retrieval manifold requires computationally expensive offline retraining via Approximate Nearest Neighbor (ANN) hard-negative mining (Qu et al., 2021; Hofstätter et al., 2021; Xiong et al., 2021). These contrastive updates are reactive and fail to offer inference-time steerability.

To regain explicit control, hybrid and sparse retrieval paradigms have re-emerged. Traditional lexical baselines like BM25 (Robertson et al., 1994) have been augmented by neural term-weighting models such as docTquery and DeepCT (Nogueira & Lin, 2019; Dai & Callan, 2019). More advanced learned sparse models project document semantics directly into the exact vocabulary space, generating interpretable, human-readable sparse vectors (Formal et al., 2021a;b; Gao et al., 2021). Alternatively, late-interaction architectures like ColBERT preserve fine-grained token-level similarities while delaying the representation bottleneck (Khattab & Zaharia, 2020; Santhanam et al., 2022; Lin et al., 2021; Luan et al., 2021).

Furthermore, dense representations natively exhibit severe anisotropy—they are constrained to narrow cones within the vector space rather than being uniformly distributed (Ethayarajh, 2019). Because latent basis vectors are highly entangled and polysemantic, applying a continuous spatial adjustment Δ_q to suppress a specific irrelevant concept simultaneously destroys unrelated semantic features, suffering from the curse of dimensionality (Beyer et al., 1999).

10.2 Sparse Autoencoders and Circuit Discovery

Recent advances have demonstrated that Sparse Autoencoders (SAEs) can effectively untangle these representations. By training a shallow autoencoder with an L_1 sparsity penalty on a wide bottleneck, SAEs project dense activations into a high-dimensional, overcomplete dictionary of monosemantic features (Cunningham et al., 2024; Bricken et al., 2023; Templeton et al., 2024; Gao et al., 2024). This allows for the precise isolation of semantic concepts, facilitating automated circuit discovery and the tracking of representational grokking (Conmy et al., 2023; Nanda et al., 2023; Wang et al., 2023).

10.3 Implicit Feedback and RL Context

To bypass the latency of offline retraining, we leverage implicit user feedback as an online correction mechanism. User interactions such as skipping top-ranked results to click on lower-ranked documents provide a natural, continuous reward signal (Joachims, 2002; Afsar et al., 2022). Formulating the retrieval correction process as an Implicit Reinforcement Learning from Human Feedback (RLHF) objective (Christiano et al., 2017) utilizes historical preference signals. However, the core premise of our methodology inherets the well-documented risks of click-driven feedback loops. User interactions are notoriously susceptible to position bias (Craswell et al., 2008) and represent a highly localized, often flawed approximation of true relevance (Joachims et al., 2017).

From a broader societal perspective, training an autonomous agent to dynamically amplify or suppress semantic concepts based purely on interaction maximization introduces the risk of algorithmic reinforcement of societal biases (Baeza-Yates, 2018; Noble, 2018). If a demographic cohort exhibits a statistically significant click-preference toward ideologically biased results, an unconstrained PPO agent represents a classic instance of RLHF reward hacking (Amodei et al., 2016; Skalse et al., 2022; Ouyang et al., 2022).

10.4 Expanded Dataset Descriptions

SciDocs (Cohan et al., 2020) evaluates direct citation prediction in scientific literature. ArguAna (Wachsmuth et al., 2018) tests the model's ability to retrieve highly abstract counter-arguments. NFCorpus (Boteva et al., 2016) provides a highly specialized medical vocabulary challenge. FiQA (Maia et al., 2018) evaluates financial question answering, which heavily relies on precise numerical and domain-specific semantic mappings. Finally, TREC-COVID (Voorhees et al., 2021) serves as a standard pandemic-era biomedical retrieval task.

10.5 Reproducibility and Source Code

To ensure reproducibility and facilitate further research, all datasets, splits, trained models, and experimental environments are made publicly accessible at: `https://anonymous.4open.science/r/IR-interpretability-RL-0632/`.
